

An Implementation of Halfedge Data Structure in Catmull-Clark Subdivision for 2-Manifold Single-sided Surface

Yu Wang

August 2015

1 Introduction

Catmull-Clark subdivision is widely applied to construct a smooth surface from an initial mesh of polygons. It is independent of the topology of initial mesh.

2 Halfedge Data Structure

An object in the 3D Euclid space can be modeled as several meshes of polygons. For a single mesh, it comprises three types of geometry elements: vertex, edge, and face. Adjacency data structure is need to store the topological information (adjacency and connectivity) between these elements. Several adjacency structures have been fully developed, including simple data structure, winged edge data structure (Baumgart, 1975), halfedge data structure (Eastman, 1982), QuadEdge Data structure (Guibas and Stolfi), and FaceEdge Data Structure (Dobkin and Laszlo, 1987).

Among all these data structures, the author chooses halfedge data structure in this project to realize Catmull-Clark subdivision, because 1) the storage size is independent of the mesh topology, and 2) it has a simple implementation. The author also extends its definition to add the ability in dealing with single-sided surfaces (or non-orientable object).

2.1 Vertex, Halfedge, and Face

The definitions and assumptions of vertex, halfedge and face follow the assumption of 2-manifold, as shown in Table 1. Element IDs are unique. When two elements fall into the same group of element, they can not have same ID. (Möbius sibling halfedges are exceptions as we discuss later). A quadrilateral face made with four halfedges and four vertices is shown in Figure 1.

Every element stores two types of information: self-information and adjacency information. As shown in Table 2. The adjacency information include adjacency in a face and adjacency between faces. The adjacency between faces include sibling links and boundary links. (And we will discussion more in the mesh section.)

	Definition	Assumption
Vertex	A 3-dimensional point.	No overlapping vertices exists in a mesh. But overlapping vertices can exist in different meshes.
Halfedge	An edge that starts from one vertex and ends at another vertex.	A halfedge connects exactly two non-overlapping vertices and it has a direction. Less than two halfedges start from the same vertex and end at the same vertex in a single mesh.
Face	A polygon that contains a loop of vertices and halfedges.	A face has at least three non-overlapping vertices so it makes a polygon. The face has to be constructed with a complete loop of halfedges with no openings.

Table 1: Definitions and assumptions of vertex, halfedge, and face

2.2 Mesh

We define a mesh as a collection of basic elements (i.e. vertex, halfedge, and face). Hashtable is implemented to represent the collection in this project, because of its constant search time for element. We construct three hashtables for all vertices, halfedges, and faces in the mesh respectively. The keys for these hashtable are element IDs and the contents are the element pointers.

The ID of a halfedge is related with the IDs of its start vertex and end vertex. In this project, we define the ID of a halfedge as start vertex ID * maximum number of vertices in a mesh + end vertex ID. This definition will guarantee a unique ID for every halfedge when they have a different start or different end vertex from other halfedges.

A mesh also includes the adjacency and connectivity for elements within. They can be classified into three groups: 1) halfedge flow in an single face, 2) face connections, and 3) boundary connections.

Figure 1: A quadrilateral face made with four halfedges

Element	Self-Information	Adjacency Information
Vertex	<ol style="list-style-type: none"> vertex ID vertex position vertex normal 	<ol style="list-style-type: none"> one outgoing halfedge on mobius connection?
Halfedge	<ol style="list-style-type: none"> edge ID 	<ol style="list-style-type: none"> start and end vertex link to parent face predecessor and successor in the parent face sibling links to adjacent face boundary links to adjacent face
Face	<ol style="list-style-type: none"> face ID face normal 	<ol style="list-style-type: none"> one side halfedge

Table 2: Definitions and assumptions of vertex, halfedge, and face

2.2.1 Halfedge Flow in One Face

A face is constructed by a loop of consecutive halfedges. The start of one halfedge is the end of its previous halfedge, and the end is the start of its next halfedge. Every halfedge contains two pointers, pointing to its previous and next halfedge respectively. Every vertex in this face will also have a pointer to its outgoing halfedge.

2.2.2 Face Connections and Sibling Links

There are two types of face connections, the normal connection and the mobius connection, as shown in Figure 2. In a typical halfedge data structure, with the assumption of double-sided surface, a pair of halfedges between two

faces are defined with opposite direction. We extend this idea to represent single-sided surface by adding another type of connection, named as mobius connection. In a mobius connection, a pair of halfedges are in same direction. The vertex on a mobius connection will also be marked for the purpose of vertex traversal in the future. In the example of Figure 2, on the top, e_1 and e'_1 are siblings to each other. On the bottom, e_1 and e'_1 are mobius siblings to each other.

One thing to point out is that mobius sibling halfedges have the same element ID. Because they have the start vertex and end vertex. However, we could check for the mobius sibling pointers in order to find all halfedges in the edge traversal of a mesh.

With the extension of mobius connection, there can be three different adjacent situations for a halfedge in a mesh: 1) it is on a normal connection and has a normal sibling, 2) it is on a mobius connection and has a mobius pointer, and 3) it lies on the boundary of the surface and does not have a sibling pointer nor a mobius pointer.

Figure 2: Normal connection (up) and mobius connection (down) between two faces

2.2.3 Boundary and Boundary Links

For halfedges on the boundary of a mesh, we connect them with boundary links. In a surface with no mobius connection, the boundary halfedges follows

a continuous flow. We can traverse the boundary when starting at one vertex, following the natural flow on the boundary, and ending at the starting vertex. Previous boundary pointers and next boundary pointers are created to link these halfedges. When a mobius connection occurs in a mesh, however, some adjacent boundary halfedges will start or end at the same vertex, which blocks the natural flow of boundary halfedges. If this happens, we build mobius boundary pointers to link these halfedges. Figure X shows an example of boundary halfedges with and without mobius connections.

!Add normal boundary links figure and mobius boundary link figures here!;

2.2.4 Build Mesh from Elements

As a conclusion of adjacency in a mesh, we need four steps in order to construct a mesh from basic elements.

Step 1: Create individual vertices. We create instances of vertices with their position and ID. The position of two vertices can be the same but their ID should always be unique.

This step takes $O(V)$ time, where V is the number of vertices in the mesh.

Step 2: Construct individual faces. To build an individual face, we create consecutive instances of halfedges, with their start and end vertices. Meanwhile, every vertex will be assigned a pointer to its outgoing halfedge when we create halfedges. For each halfedge, we then add the previous and next pointers to its previous halfedge and next halfedge respectively.

This step takes $O(E)$ time, where E is the number of halfedges in the mesh.

Step 3: Build sibling links. For every halfedge, we need to find if there exists a sibling or mobius sibling from other faces in this mesh. If its start vertex is the same with the end of another halfedge, and its end vertex is the same with the start of another halfedge, we then find a sibling. If it has the same start and end vertex with another halfedge, we then find a mobius sibling.

In this project, with the implementation of hashtable, the ID of a halfedge is related with its start vertex ID and end vertex ID. The mobius sibling link is actually generated in step 2. When we create the halfedge, if its ID is equal to a halfedge that we created before, we know they are mobius siblings. The search of normal sibling is also in constant time because we can calculate the ID of its sibling halfedge knowing that their start and end vertex are reversed.

This step takes $O(E)$ time, where E is number of halfedges in the mesh.

Step 4: Build boundary links. After step 3, if a halfedge does not have a sibling or mobius sibling, it lies on the boundary of this mesh. We need to build the boundary links to these halfedges.

To do this, we need a counter to keep track of how many times we cross a mobius connection. We 1) set counter equal to zero and start from one halfedge on the boudary, 2) we go to its next halfedge if the counter is even, or its previous halfedge if the counter is odd, 3) we then go to its the sibling or moibus sibling, the counter increase by 1 if it is a mobius sibling, 4) check if the current halfedge is on boundary, if not, we repeat 2) and 3) until we reach to one, and 5) this boundary halfedge shares one vertex with our last boundary halfedge, so we can build boundary links between them, and 6) we repeat 1) to 5) to build bounary links until we reach the starting boundary halfedge in 1). From 1) to 6), one boundary loop of this mesh is built. And we move on to build other loops by repeating 1) to 6), until every boundary halfedges have boundary links to its adjacent boundaries.

This step takes $O(E)$ time, where E is the number of halfedges in the mesh.

Now this mesh contains everything that we need to start a Catmull-Clark subdivision. In total, it takes $O(E)$ time from step 1 to step 4.

2.3 Mesh Operations

Building from basic elements is not the only way to create the initial mesh for Catmull-Clark subdivison. A new mesh can also be made by the following mesh operations: 1) copy a mesh, 2) 3D transformation of a mesh, and 3) merging the boundaries for two meshes.

2.3.1 Copy a Mesh

In order to make a copy, we create one element instance for every element that belongs to the original mesh. The copy of a mesh will keep the adjacency for elements and positions of vertices. Therefore, new element instances remain exact same adjacency information as the original mesh, except that the element ID is different and pointers are pointing to the new instances.

2.3.2 Mesh Transformation

In a 3D transformation, the positions for all vertices in the mesh will perform transformation. The adjacency of original mesh remains the same, so halfedges and faces will transform at the same time while vertices transform. Typically, for linear transformations, we multiply the transformation matrix to the position of every vertex from the original mesh.

2.3.3 Merging Meshes

Meshes can be merged into a new mesh if sibling links can be made between some of the boundary halfedges that belongs them. This merge of boundary halfedge will keep the new mesh as a 2-manifold. We also want the elements ID from these meshes stays different, so no collision occurs after we merge them together.

Two types of mesh merging are implemented in this project: automatic merging and manual merging. In automatic merging, we define a very small tolerance value. If any pair of vertices on the boundary of the two meshes have a distance smaller than the tolerance, we check if their boundary halfedges can be merged with sibling links. If they do, we merge them, continue to trace along the boundaries of these two meshes and merge boundary halfedges until we can't.

In manual merging, we force to merge boundaries from two meshes even if the distance of their vertices are larger than tolerance. In practice, we have four ways to perform the manual merging. Assume we would like to force merge the boundary of Mesh 1 and Mesh 2, we can apply one of the following strategies:

- 1) Vertex positions in mesh 1 remain the same after merging. The boundary faces on Mesh 2 extend to the boundary of Mesh 1.
- 2) The opposite of 1).
- 3) Use the arithmetic mean position for vertex from Mesh 1 and Mesh 2 as the final vertex position after merging. The boundary faces from Mesh 1 and Mesh 2 both extend to these new vertex positions.
- 4) Build new faces between the two meshes and the vertex positions for Mesh 1 and Mesh 2 remain the same.

2.4 Mesh Traversals

Catmull-Clark subdivision also requires two types of traversals in a mesh: 1) traversal around a face, and 2) traversal around a vertex. Traversal around a face is necessary to build face points and calculate face normals in the face. Traversal around a vertex is necessary to build vertex points and calculate vertex normals in the face.

2.4.1 Traversal Around Face

The traversal around a face lead to all the edges and vertices belong to this face. It starts from one side halfedge of this face, follows the halfedge flow, and ends at starting the halfedge of the traversal. Traversals of all faces in a mesh takes $O(E)$ time, where E is the number of faces in the mesh.

2.4.2 Traversal Around Vertex

The traversal around a vertex lead to all edges and faces that contains this vertex. The traversal of a vertex need to consider two issues: 1) is this vertex on a boundary, and 2) is this vertex on a mobius connection. This makes four different types of vertex traversals. See Figure 3 - 6 for examples.

In the vertex traversal without boundary and mobius issue, we start from one outgoing halfedge of this vertex. We continue to go to the next outgoing halfedge by going to the successor of its sibling until we hit the first outgoing halfedge. In the example of Figure 3, if start and end at halfedge e_1 , the sequence of traversal is: e_1 (sibling link to) e'_1 (successor link to) e_2 (sibling link to) e'_2 (successor link to) e_3 (sibling link to) e'_3 (successor link to) e_4 (sibling link to) e'_4 (successor link to) e_1 .

In order to address the issue of a vertex on boundary, instead of using sibling links, we use boundary links. In the example of Figure 5, we have a boundary e'_4 to e_2 . If start and end at halfedge e_1 , the sequence of traversal is: e_1 (sibling link to) e'_1 (successor link to) e_2 (boundary link to) e'_4 (successor link to) e_1 .

To address the issue of vertex on a mobius connection, instead of using normal links, we use mobius links. At the same time, we switch between the successor and predecessor to the sibling every time we hit a mobius connection. In the example of Figure 3, e_1 to e'_1 and e_3 to e'_3 have mobius siblings rather than normal sibling. If start and end at halfedge e_1 , the sequence of traversal is: e_1 (mobius sibling link to) e'_1 (predecessor link to)

e_2 (sibling link to) e'_2 (predecessor link to) e_3 (mobius sibling link to) e'_3 (successor link to) e_4 (sibling link to) e'_4 (successor link to) e_1 .

If boundary and mobius connection both occur, we use a combination of the two methods above. In the example of Figure 3, e_1 to e'_1 and e_3 to e'_3 have mobius siblings rather than normal sibling and we have a mobius boundary connection between e'_4 and e_2 . If start end end at halfedge e_1 , the sequence of traversal is: e_1 (mobius sibling link to) e'_1 (predecessor link to) e_2 (mobius boundary link to) e'_4 (successor link to) e_1 .

As a summary of the four different situations above, in a vertex traversal, we 1) start the traversal from with one outgoing halfedge of the vertex, 2) go to sibling or boundary link halfedge, 3) go to the next or previous halfedge that contains the vertex as one end, and 4) repeat 2) and 3) until we reach to the starting outgoing halfedge. This vertex traversal runs in $O(E)$ time, where E is the total number of halfedges in the mesh.

3 Catmull-Clark Subdivision

Catmull-Clark subdivision is a recursive call on a mesh that we build in section X. For each level of Catmull-Clark subdivision, we divide every polygon face in the mesh into N quadrilateral faces, where N is the number of halfedges of the polygon face. The new vertices for these sub-faces can be classified into three groups: 1) face points, 2) edge points, and 3) vertex points. We also need to add adjacency information to new sub-faces so that they be subdivided for the next level. Therefore, each level of subdivision is done in two steps: 1) compute the positions of new vertices, and 2) compile a new mesh given the new vertices.

3.1 Compute New Vertex Positions

There are three steps to compute the positions of vertices in the new mesh: 1) make new face points, 2) make new edge points, and 3) make new Vertex Points. Apart from finding the positions for these new vertices, we also need to assign unique IDs for them so no collision will occur for the new mesh.

3.1.1 Face Points

Face points are related with faces from the mesh. For every face in the mesh, the position of its face point is defined as the average for positions of all vertices belong to this face. If we label the face point as f and vertices of

this face as v_i , the equation to calculate face point is,

$$v_f = \frac{v_1 + v_2 + \dots + v_n}{n}$$

Therefore, in order to get the face point position, we can do a traversal around a face, find all vertices and get the average of their positions.

3.1.2 Edge Points

Edge points are related with halfedges from the mesh. In this project, we used the idea from (Reference) and define the sharpness of a halfedge as either infinite sharp or smooth. Depends on the position and sharpness of the edge, we have two ways to calculate the edge point.

If a halfedge does not lie on the boundary, it has a sibling link or mobius link to another halfedge. For the halfedges that are not marked as sharp, the position of edge point of a halfedge is the average of its start vertex position, end vertex position, the face point position of the face it belongs to, and the face point position of the face its sibling or mobius sibling belongs to. If we label the edge point as v_e , the start and end vertices as v_1 and v_2 , the face point of its face is v_3 and the face point of its sibling face is v_4 , the equation to calculate edge point is,

$$v_e = \frac{v_1 + v_2 + v_3 + v_4}{4}$$

If a halfedge lie on the boundary or it is marked as sharp, the position of the edge point is the average of its start vertex position and end vertex position. If we label the edge point as v_e , the start and end vertices as v_1 and v_2 , the equation to calculate edge point is,

$$v_e = \frac{v_1 + v_2}{2}$$

3.1.3 Vertex Points

Vertex points are related with vertices from the mesh. Depends on the number of sharp halfedge linking with this vertex, we have three ways to calculate vertex points.

1) A vertex with three or more incident sharp edges is called a corner, the new vertex point has same position with the original vertex. If we label the

vertex point as v_p , the original vertex as v_1 , the equation to calculate vertex point is,

$$v_p = v_1$$

2) A vertex with two incident sharp edges is called a crease vertex. If we label the vertex point as v_p , the original vertex as v_1 and the two halfedges are labeled with v_1v_2 and v_1v_3 . the equation to calculate vertex point is,

$$v_p = \frac{v_2 + 6v_1 + v_3}{8}$$

3) A vertex with less than two sharp edges is a normal vertex. There are two different approaches in calculating the vertex point for a normal vertex. We label the vertex point as v_p , the original vertex point as v_1 , the average for all midpoints of edges that contains the original vertex is v_2 , the average for all edge points of edges that contains the original vertex is v'_2 , the average of the face points of all faces adjacent to the old vertex point as v_3 , and the valance of the vertex (the number of edges adjacent) as n . Catmull-Clark (Reference) defined vertex point as

$$v_p = \frac{(n-3)v_1 + 2v_2 + v_3}{n}$$

While DeRose (Reference) defined vertex point as

$$v_p = \frac{(n-2)v_1 + v'_2 + v_3}{n}$$

The difference between these two equations is very small. On one hand, with Catmull-Clark's equation, when we meet a vertex of valance 3, e.g. a corner of a cube, the weight for the original point becomes zero. This does not produce a good subdivision. Therefore, we apply $n = 4$ when the valance equal to 3. On the contrary, DeRose's equation is applicatable to all vertices. On the other hand, compared to DeRose's equation, Catmull-Clark's equation has one more weight on the edge point average and one less weight on the original vertex, meaning that vertex points are more related with the neighbours of the original vertex.

In this project, we used DeRose's equation to calculate vertex point for a normal vertex.
